ON THE WEIGHTED EUCLIDEAN
MATCHING PROBLEM IN $\mathbb{R}^d$

Abstract. A partitioning algorithm for the Euclidean matching problem in $\mathbb{R}^d$ is introduced and analyzed in a probabilistic model. The algorithm uses elements from the fixed dissection algorithm of Karp and Steele (1985) and the Zig-Zag algorithm of Halton and Terada (1982) for the traveling salesman problem. The algorithm runs in expected time $n(\log n)^{p-1}$ and approximates the optimal matching in the probabilistic sense.

1. Introduction. Consider for $x_1, \ldots, x_n \in \mathbb{R}^d$, $d \geq 1$, the weighted Euclidean matching functional

$$(1.1) \qquad L(x_1, \ldots, x_n) = \min_{\sigma \in \mathcal{S}_n} \sum_{i=1}^{m} |x_{\sigma(2i-1)} - x_{\sigma(2i)}|$$

where $\mathcal{S}_n$ is the set of all permutations of $\{1, \ldots, n\}$, $m = [n/2]$, and $\| \, \|$ is the Euclidean norm. L is a quasiadditive functional, i.e. L is subadditive, continuous, and there exists an approximating superadditive functional $\widehat{L}$ with $\widehat{L} \leq L + 1$ on $[0, 1]^d$. $\widehat{L}$ is defined by the corresponding boundary matching functional, which allows matching to boundary points (cf. Redmond and Yukich (1994)). Therefore, the general version of the Beardwood, Halton, and Hammersly (BHH) Theorem of Redmond and Yukich (1994) implies for any iid sequence (X_i) on $[0, 1]^d$ with $P^{X_i} = \mu$ that

$$(1.2) \qquad \lim_{n \to \infty} \frac{L(X_1, \ldots, X_n)}{n^{(d-1)/d}} = \beta(L) \int f(x)^{(d-1)/d} \, \lambda^d(dx)$$

in the sense of complete convergence, where f is the density of the Lebesgue continuous part of μ.

In this paper we introduce a partitioning algorithm for the Euclidean matching problem; we prove that it approximates the optimal solution in a probabilistic model and operates in expected running time $n(\log n)^{p-1}$. For the construction of the algorithm we combine elements of the fixed dissection algorithm of Karp (1977), Karp and Steele (1985) and of the Zig-Zag algorithm of Halton and Terada (1982) as designed for the traveling salesman problem (TSP). In the two-dimensional case $p = 2$ an alternative partitioning algorithm analogue to Karp's (1977) bisection algorithm for the TSP, where cells are constructed with a deterministic number of points, has been introduced and analyzed in Rüschendorf and Sachs (1998) for general distributions. Dyer and Frieze (1984) considered a related fixed partitioning scheme for the uniform matching problem in $d = 2$. In his recent book on Euclidean optimization problems, Yukich (1998) describes a general approach to an approximation result of subadditive Euclidean functionals (satisfying some conditions) by a partitioning heuristic as in Karp's TSP-heuristic (see Theorem 5.8). An essential implicit assumption in this approach (relation (5.15)) which describes the approximation of the heuristic by the independent sum of the values of the functional at the subcubes is not, however, discussed in this book. To establish a related estimate is the main work in this and also in the previous papers on this subject.

In contrast to the TSP which is an NP-problem the Euclidean matching can be formulated as a linear programming problem and, therefore, has a polynomial running time exact solution of order n^3. (The fastest known exact solution for $d = 2$ is of order $O(n^{2.5}(\log n)^4)$; see Vaidya (1989).) But the improvement of the order of the running time to $n(\log n)^{d-1}$ is considerable and of practical interest also for this combinatorial optimization problem. We analyze the partitioning algorithm in the random model where $\{X_i\}_{1 \le i \le n}$ are independent random vectors uniformly distributed on the unit cube $Q = [0,1]^d$. In the final remark we extend this analysis to general distributions on $[0,1]^d$.

2. Introduction of the partitioning algorithm. For n points $x_1, \ldots \ldots, x_n \in [0,1]^d$ let T_n denote an optimal Euclidean matching with value $|T_n| = L(x_1, \ldots, x_n)$. The construction of the partitioning algorithm I_n uses the following steps:

(a) *Subdivision of the cube.* $Q = [0,1]^d$ is divided into $M := m^d$ congruent cubes of side length $1/m$. Here

$$(2.1) \qquad m = 2\left(\left[\frac{1}{2}\left(\frac{2n}{\log \sigma(n)}\right)^{1/d}\right] + 1\right)$$

with an increasing function σ satisfying $\sigma(n) \to \infty$ as $n \to \infty$. Then

$$(2.2) \qquad M = m^d \sim \frac{2n}{\log \sigma(n)}.$$

Any side of Q is partitioned into m^{d-1} congruent $(d-1)$-dimensional cubes and generates a cubic lattice with M d-dimensional cubes C_j, $1 \leq j \leq M$.

(b) *Ordering of the* C_j. The M cubes C_j are ordered by the Zig-Zag algorithm of Halton and Terada (1982)—in a time of order M resulting in a sequence $C_1 \ldots C_M$ (after relabeling of the cells). This ordering is established as follows: For each lattice vector $\mathbf{a} = (a_1, \ldots, a_d)$ with $a_i \in L := \{0, 1, \ldots, m-1\}$ define the cell

$$(2.3) \qquad C(\mathbf{a}) := \left\{ x \in [0,1]^d : \frac{a_i}{m} \leq x_i < \frac{a_i + 1}{m}, \; 1 \leq i \leq d \right\}.$$

This defines a bijection of the M lattice vectors $\mathbf{a}$ to the cells C_i, $1 \leq i \leq M$. So an ordering of the lattice vectors $\mathbf{a}$ induces an ordering of the cells C_i. Define

$$r_i = r_i(\mathbf{a}) = (-1)^{1 + a_1 + \ldots + a_{i-1}}, \quad 2 \leq i \leq d.$$

For each lattice vector $\mathbf{a}$ there exists at most one t such that

$$(2.4) \qquad a_i + r_i \notin L \quad \text{for } i = t+1, \ldots, d, \quad a_t + r_t \in L \quad \text{and} \quad t \geq 3.$$

If a t with (2.4) exists, then define the successor of $\mathbf{a}$ as $\mathbf{a}' = \mathbf{a} + r_t \mathbf{e}_t$ where $a_i' = a_i$, $i \neq t$, and $a_t' = a_t + r_t$ and $\mathbf{e}_t$ is the unit vector in the tth coordinate direction.

If no t with (2.4) exists then define the successor $\mathbf{a}'$ of $\mathbf{a}$ by:

$$(2.5) \quad \mathbf{a}' = \begin{cases} \mathbf{a} - \mathbf{e}_1 & \text{if } (a_1 = 1, \; a_2 = 0) \text{ or } (a_1 > 1, \; a_2 \text{ even}), \\ \mathbf{a} + \mathbf{e}_1 & \text{if } (a_1 = 0, \; a_2 = m-1) \text{ or } (0 < a_1 < m-1, \; a_2 \text{ odd}), \\ \mathbf{a} - \mathbf{e}_2 & \text{if } (a_1 = 1, \; a_2 \neq 0 \text{ even}) \text{ or } (a_1 = m-1, \; a_2 \text{ odd}), \\ \mathbf{a} + \mathbf{e}_2 & \text{if } (a_1 = 0, \; a_2 < m-1). \end{cases}$$

Halton and Terada (1982) prove that this definition generates a tour through the set of lattice vectors $\mathbf{a}$ in L^d.

Fig. 1. Zig-Zag tour in $d = 2$, $m = 4$

(c) *Optimal matching within C_j.* In the first step an optimal matching is constructed in C_1. If the number of points in C_1 is odd then the nonmatched point is matched with any point in C_2. Then the remaining points in C_2 are optimally matched. The next cell is C_3 and the ordering of the cells by the Zig-Zag algorithm is followed also when no points in a cell C_i are present until finally an optimal matching is generated in C_M.

Let I_n denote the matching generated by this partitioning algorithm and let $\ell(I_n)$ denote the value of this matching which consists of the sum of the lengths of the optimal matchings within C_i and additionally the sum of the lengths of connections of possibly unmatched points between neighbouring cells.

Fig. 2. ×—× and ×- - -× describe T_n; ×—× and ×-·--× describe I_n

Note that two neighbouring blocks have $d-1$ edges of length $1/m$ and one edge of length $2/m$. The diameter is

$$(2.6) \qquad \frac{1}{m}((d-1)+2^2)^{1/2} = \frac{1}{m}\sqrt{d+3}.$$

Therefore, these connections contribute at most $M(1/m)\sqrt{d+3}$ to the value of the matching I_n. If a cell is empty then the diagonal length is contained in the bound above.

3. Running time of the partitioning algorithm. The running time of the partitioning algorithm is determined by two components. Firstly, the running time of the Zig-Zag algorithm to produce the sequential order of the cubes C_j. By Halton and Terada (1982) this is of order

$$(3.1) \qquad O(M) = O\left(\frac{n}{\log \sigma(n)}\right).$$

In each cell C_i an optimal matching is produced. We assume that we can solve a Euclidean matching problem with k points in time $f(k) :=$

Dk^p with constants p, D. This is fulfilled for $p = 3$ by Papadimitriou and Steiglitz (1982, Theorem 11.3, Problem 14). Improvements of this order to $O(n^{2.5}(\log n)^4)$ are given in Vaidya (1989) to some more general class of geometric algorithms in dimension two. By the assumption that $X_1, \ldots, X_n$ are independent, uniformly distributed on $[0, 1]^d$, the numbers n_i of points in C_i are binomially distributed random variables:

$$P(n_i = k) = \binom{n}{k}\left(\frac{1}{m^d}\right)^k\left(1 - \frac{1}{m^d}\right)^{n-k}.$$

With the bound $f(k) = Dk^p$ for the optimal matching of k points we obtain

$$(3.2) \qquad Ef(k_i) \sim Dn^p\left(\frac{1}{m^d}\right)^p.$$

The optimal matching of the $M = m^d$ cubes therefore needs the expected running time

$$\sum_{i=1}^{m^d} Ef(k_i) \sim Dn\left(\frac{n}{m^d}\right)^{p-1}.$$

Choosing $\sigma(n) = \exp(2 \log n)$ we obtain

$$(3.3) \qquad \sum Ef(k_i) = O(n(\log n)^{p-1}).$$

The variance of $f(k_i)$ is of order

$$(3.4) \qquad \operatorname{Var} f(k_i) \sim D^2 n^{2p}\left(\frac{1}{m^d}\right)^{2p},$$

which implies by McDiarmid's inequality

$$\operatorname{Var}\left(\sum_{i=1}^{m^d} f(k_i)\right) \leq \sum \operatorname{Var} f(k_i) \sim D^2 n^{2p}\left(\frac{1}{m^d}\right)^{2p-1} = O(n(\log n)^{2p-1})$$

for the choice of $\sigma(n)$ as above. Since the Zig-Zag algorithm has a deterministic upper bound $O(n/\log n)$, we obtain

THEOREM 3.1. *In the random uniform model the partitioning algorithm with the choice $\sigma(n) = \exp(2 \log n)$ operates in expected running time $O(n(\log n)^{p-1})$. The variance of the running time is $O(n(\log n)^{2p-1})$.*

In comparison to the bisection algorithm as considered in Rüschendorf and Sachs (1998) for $d = 2$ we have for the fixed dissection algorithm in this paper only a random running time behaviour with expectation of order $O(n(\log n)^{p-1})$. Under a stronger condition on $\sigma(n)$ Halton and Terada (1982) derive an a.s. running time behaviour of the corresponding algorithm in the TSP which could also be given in this context.

4. Approximation of the optimal matching. In the first part of this section we compare the value of the partitioning algorithm with the value of the optimal matching and establish an upper estimate for $\ell(I_n) - |T_n|$, where T_n denotes the optimal matching for $\{X_1, \ldots, X_n\}$. For each face F_{ij}, $1 \leq j \leq 2d$, of the cube C_i we consider the set of marks M_{ij} where an edge of T_n which connects a point of $C_i \cap \{X_1, \ldots, X_n\}$ to some point in a different cube intersects F_{ij}.

According to the construction of our partitioning algorithm an optimal matching is constructed in cell C_i and a possibly unmatched point in C_i is connected to an arbitrary point in the next nonempty cell according to the Zig-Zag tour through the cells. It is not obvious how to bound $\ell(I_n)$ from above by the length of the optimal matching T_n plus some correction term. To that purpose we introduce a matching $\widehat{T}_n(i)$ of the points in cell C_i which is induced by the matchings T_{ij} of the marks M_{ij} in the faces of C_i by the following steps:

Firstly, we match those points in C_i where the corresponding marks generated by the optimal matching T_n in the faces are connected in the optimal matching T_{ij} of M_{ij}. Then the points in neighbouring faces, which remained unmatched in the first step, are matched.

Finally, we use the part of the matching of points inside C_i by the optimal matching T_n.

Fig. 3. ×—× describes T_n, ×- - -× describes new parts of $\widehat{T}_n(i)$, $\cdots$ describes T_{ij}

Obviously, the value of this matching $\widehat{T}_n(i)$ is an upper bound for the value of the optimal matching in cell C_i used in our partitioning algorithm I_n. We will next prove that the length of the induced total matching $\widehat{T}_n = \sum \widehat{T}_n(i)$ can be estimated from above by the value of the optimal matching T_n plus some terms of lower order.

By construction we obtain from the triangle inequality (see also Figure 3)

$$(4.1) \qquad \ell(I_n) \le |\widehat{T}_n| + M\frac{\sqrt{d+3}}{m}$$

$$\le |T_n| + 2\sum_i \sum_j |T_{ij}| + M\frac{\sqrt{d+3}}{m} + \sum_{i=1}^{m^d} K_2(2d)^{(d-1)/d}\frac{1}{m}$$

where the term $M\sqrt{d+3}/m$ is from the matching of the remaining points in the cells C_i connected to the neighbour cells and where the last term comes from the matching of the points which remain unmatched in the faces in the first step with a universal constant K_2 and with the scaling $1/m$ for the side length (see Figure 3).

Here we use the fact that by a simple induction argument (see Karp and Steele (1985)) the length of an optimal matching of n points in the d-dimensional unit cube is bounded above by

$$(4.2) \qquad\qquad K_2 n^{(d-1)/d} \quad \text{for some } K_2 > 0.$$

Since the marks M_{ij} are matched in the $(d-1)$-dimensional faces of side length $1/m$, we obtain

$$(4.3) \qquad \ell(I_n) \le |T_n| + 2\sum_{i=1}^{m^d}\sum_{j=1}^{2d} K_2 |M_{ij}|^{(d-2)/(d-1)}\frac{1}{m}$$

$$+ M\frac{\sqrt{d+3}}{m} + \sum_{i=1}^{m^d} K_2(2d)^{(d-1)/d}\frac{1}{m}.$$

Since $\sum_{i=1}^{m^d}\sum_{j=1}^{2d}|M_{ij}| \le 2n$ and $x \mapsto x^{(d-2)/(d-1)}$ is concave we obtain

$$\ell(I_n) - |T_n| - M\frac{\sqrt{d+3}}{m}$$

$$\le 2\sum_{i=1}^{m^d}\sum_{j=1}^{2d} K_2\left(\frac{2n}{dm^d}\right)^{(d-2)/(d-1)}\frac{1}{m} + K_2 m^d(2d)^{(d-1)/d}\frac{1}{m}$$

$$= K_1(2n)^{(d-2)/(d-1)}m^{1/(d-1)} + K_2 m^{d-1}$$

$$\sim K_1(2n)^{(d-2)/(d-1)}\left(\frac{2n}{\log\sigma(n)}\right)^{1/(d-1)} + K_2\left(\frac{2n}{\log\sigma(n)}\right)^{(d-1)/d}$$

$$= O(n^{(d-1)/d}(\log\sigma(n))^{-1/(d(d-1))}).$$

With $M = m^d \sim 2n/\log\sigma(n)$ we obtain

$$\ell(I_n) \le |T_n| + O(n^{(d-1)/d}(\log\sigma(n))^{-(d-1)/d})$$
$$+ O(n^{(d-1)/d}(\log\sigma(n))^{-1/(d(d-1))}).$$

Thus the value of the partitioning algorithm I_n is bounded from above by the value of the optimal matching plus some deterministic bound of lower order.

THEOREM 4.1. *The length of the partitioning algorithm for Euclidean matching of n points $X_1, \ldots, X_n$ in $[0,1]^d$ is estimated from above by*

$$(4.4) \qquad \ell(I_n) \leq |T_n| + O(n^{(d-1)/d}(\log \sigma(n))^{-1/(d(d-1))}).$$

To estimate the relative error compared to the optimal matching T_n we use the following lemma.

LEMMA 4.2. *There exist constants $A, C > 0$, $0 < \varrho < 1$ such that in the random data model $X_1, \ldots, X_n$,*

$$(4.5) \qquad P(|T_n| < An^{(d-1)/d}) \leq C\varrho^n \quad \text{for all } n.$$

Proof. As $|T_n|$ is a quasiadditive functional one obtains from Rhee (1993)

$$P(|T_n - ET_n| \geq t) \leq C \exp\left(-\frac{1}{Cn}\left(\frac{t}{K_1}\right)\right)^{2d/(d-1)}$$

for some constants $C, K_1 > 0$. Further, for $\{X_i\}$ independent and uniformly distributed on $[0,1]^d$ one obtains

$$E \min\{|X_i - X_j| : i, j \leq n, \ i \neq j\} \geq cn^{-1/d}$$

for some $c > 0$. This implies the lower bound

$$ET_n \geq \frac{n}{2}cn^{-1/d} = \frac{c}{2}n^{(d-1)/d}.$$

Therefore,

$$
\begin{aligned}
P(T_n < An^{(d-1)/d}) &= P(T_n - ET_n < An^{(d-1)/d} - ET_n) \\
&\leq P(ET_n - T_n > (c/2 - A)n^{(d-1)/d}) \\
&\leq P(|ET_n - T_n| > Bn^{(d-1)/d}) \\
&\leq C \exp\left(-\frac{1}{Cn}\left(\frac{Bn^{(d-1)/d}}{K_1}\right)^{2d/(d-1)}\right) \\
&= C \exp(-Dn) = C\varrho^n \quad \text{with } \varrho = e^{-D}
\end{aligned}
$$

(all constants are > 0). ∎

As a result we obtain complete convergence of $\ell(I_n)/T_n$ to 1.

THEOREM 4.3. *In the random data model the relative length of the matching of the partitioning algorithm to the optimal length converges completely to one:*

$$\ell(I_n)/|T_n| \xrightarrow{c} 1,$$

i.e. for all $\varepsilon > 0$ we have $\sum_{n=1}^{\infty} P(\ell(I_n)/|T_n| \geq 1 + \varepsilon) < \infty$.

Proof. Using the estimates in Theorem 4.1 and Lemma 4.2 we obtain

$$P(\ell(I_n)/|T_n| \geq 1 + \varepsilon) \leq P(|T_n| < An^{(d-1)/d})$$
$$+ P(\ell(I_n) - |T_n| \geq \varepsilon An^{(d-1)/d})$$
$$\leq C\varrho^n + P(\ell(I_n) - |T_n| \geq \varepsilon An^{(d-1)/d}).$$

Therefore,

$$\sum_{n=1}^{\infty} P(\ell(I_n)/|T_n| \geq 1 + \varepsilon)$$

$$\leq C \sum_{n=1}^{\infty} \varrho^n + \sum_{n=1}^{\infty} P(\ell(I_n) - |T_n| \geq \varepsilon An^{(d-1)/d}) < \infty$$

since the last sum has only finitely many nonzero summands. ∎

REMARK (General distributions). The normalized minimum matching functional converges also for general distributions (see (1.2)). The estimate in Theorem 4.1 is valid for any set of deterministic points in $[0,1]^d$. Therefore, by (1.2) the normalized partitioning algorithm converges completely to the same constant $\beta(L) \int f(x)^{(d-1)/d} \lambda^d(dx)$ as well. This implies complete convergence of the quotient $\ell(I_n)/|T_n| \to 1$ (see also Yukich (1998), proof of Theorem 5.8). Therefore, we obtain an approximation of the matching functional by the partitioning algorithm in the probabilistic sense for general distributions on $[0,1]^d$ with nontrivial Lebesgue continuous part. ∎

As a result of the analysis we deduce that the partitioning algorithm yields an approximative optimal matching and uses expected running time $O(n(\log n)^{p-1})$. This improves considerably on the running time of exact deterministic algorithms.
