Abstract. We discuss two different methods of Altman for solving systems of linear equations. These methods can be considered as Krylov subspace type methods for solving a projected counterpart of the original system. We discuss the link to classical Krylov subspace methods, and give some theoretical and numerical results on their convergence behavior.

1. Introduction. Consider a system of linear equations

\begin{equation}
Ax = b,
\end{equation}

where $A$ is supposed to be hermitian positive definite of order $p$, and (without loss of generality) the right-hand side is supposed to be of euclidean norm $\|b\| = 1$. In a series of papers [1–6], Altman considers the associated problem

\begin{equation}
Ay = (Ay, b)b,
\end{equation}

which, with the help of the orthogonal projector $P = I - bb^*$ onto the orthogonal complement of $b$, can be equivalently written as $PAy = 0$. Notice that the set of solutions of (2) is given by the set of scalar multiples of $A^{-1}b$, and hence, given any non-trivial solution $y$ of (2), a solution of (1) is given by $x = y/(Ay, b)$. Corresponding to (2), Altman also considers the linear operator

\[
r(y) := PAy = -P(b - Ay),
\]

coinciding up to a sign with the projected residual of (1).

In the above-mentioned papers, Altman proposes essentially two iterative methods giving approximate non-trivial solutions of (2) (and hence of (1) after normalization). Given a $y_0$ with $(y_0, b) \neq 0$, the first method presented in [1, Eqns. (5) and (6)] and further analyzed and generalized in [6] minimizes

\[2000 \text{ Mathematics Subject Classification: 65F10, 65E05.}
\]
\[\text{Key words and phrases: conjugate gradient method, Krylov subspace methods.}\]
the norm of the projected residual

\[ y_{n+1} = y_n + \alpha_n r(y_n), \quad \alpha_n = \arg \min \{ \| r(y_n + \alpha r(y_n)) \| : \alpha \in \mathbb{R} \}, \]

leading to a generalized method of minimal residuals. In the second method (see also [10, pp. 132–139]), Altman considers a quadratic form [2, Eqn. (7)] closely related to the quadratic form

\[ G(y) := \left( A - \frac{bb^*}{(A^{-1}b, b)} \right) y, y \]

(Altman’s quadratic form \( F \) involves \( r \) and its inverse, defined on the orthogonal complement of \( b \); see the Appendix for further details). It is not difficult to check using formula (13) below that \( G(y) \geq 0 \), and \( G(y) = 0 \) if and only if \( y \) is a solution of (2). Then the so-called generalized steepest descent method introduced in [2, Eqns. (10) and (11)] and further analyzed in [5] is given by

\[ y_{n+1} = y_n + \alpha_n r(y_n), \quad \alpha_n = \arg \min \{ G(y_n + \alpha r(y_n)) : \alpha \in \mathbb{R} \}. \]

For completeness, let us mention that relaxation approaches for these methods have been discussed in [3, 4], and additional projections on other subspaces have been investigated in [5, 6].

Both methods (3) and (5) may be considered as restarted versions (after one iteration) of generalized Krylov methods: here one minimizes on projected counterparts of the Krylov subspaces

\[ K_n(A, c) := \text{span}(c, Ac, \ldots, A^{n-1}c) \]

with the starting vector \( c = b - Ay_0 \). Indeed, (3) is the single-step version of the method

\[ y_n = y_0 + \arg \min \{ \| r(y_0 + u) \| : u \in K_n(PA, P(b - Ay_0)) \}, \]

referred to in what follows as AMinRes, and (5) is the single-step version of the method

\[ y_n = y_0 + \arg \min \{ G(y_0 + u) : u \in K_n(PA, P(b - Ay_0)) \}, \]

referred to in what follows as ACG. To our knowledge, these latter methods have not been considered before.

The purpose of this note is to show that both approaches (6) and (7) (and thus also Altman’s work) are mathematically equivalent to the classical algorithms of minimal residuals (MinRes) and conjugate gradients (CG), applied to the hermitian and semi-positive-definite matrix

\[ \tilde{A} := PA^*P. \]

As a consequence, we find coupled short term recurrences for the vectors \( y_n \) of (6) and (7), as well as error estimates involving the condition number of the matrix \( A \), derived already in a different manner by Altman [1, Eqn. (16)],
Altman’s methods revisited

[2, Eqn. (12)]. In particular, we establish interlacing properties of the corresponding eigenvalues, and conclude that both methods (6) and (7) behave always at least as well as the corresponding classical counterparts MinRes and CG, with an improvement of the speed of convergence only occurring for particular right-hand sides \( b \). In this context it is interesting to observe that already Altman suggested first transforming the original system (1) into \( Ax' = b' \), \( b' = b - Ax^* \), with \( x' = x - x^* \), where \( x^* \) is some arbitrary vector, but he did not give any further device how to choose this vector \( x^* \).

The remaining part of the paper is organized as follows: in Section 2 we explicitly state and prove the above equivalence claim, and discuss the behavior of MinRes/CG applied to consistent hermitian but singular systems. In Section 3 we study convergence properties of Altman’s methods, both in the range of linear and super-linear convergence. Section 4 is devoted to the recursive computation of the iterates of Altman’s methods. Since the analysis for (6) and (7) is quite similar, we concentrate in this part only on (7). In Section 5 we present some numerical experiments confirming the theoretical observations of Section 3. Finally, in the Appendix we discuss two quadratic forms.

2. The equivalence. With the hermitian semi-positive-definite matrix \( \tilde{A} = PAP \) as in (8), consider the system of linear equations

\[
\tilde{A}\tilde{x} = \tilde{b} := -r(y_0) = -PAy_0.
\]

In the following statement we give the exact link between Altman’s algorithms (and their multi-step versions (6) and (7)) and classical algorithms like MinRes and CG, applied to (9).

**Theorem 1.** The sequence \((y_n - y_0)_{n \geq 0}\) with \( y_n \) as in (6) is obtained by applying the MinRes algorithm with starting vector 0 to the system (9). Similarly, the sequence \((y_n - y_0)_{n \geq 0}\) with \( y_n \) as in (7) is obtained by applying the CG algorithm with starting vector 0 to (9).

Before presenting a proof of Theorem 1, let us take a closer look at the behavior of MinRes/CG applied to (9). Since \( b^*b = 0 \), we obtain

\[
\tilde{b} \in \text{span}(b)^\perp = \text{Ker}(\tilde{A})^\perp = \text{range}(\tilde{A}),
\]

and hence (9) is consistent, though its matrix of coefficients is singular. The performance of Krylov subspace methods applied to inconsistent singular systems has been discussed by several authors (see for instance [11] and the references therein). However, for consistent hermitian singular systems, the behavior is easily predictable: it is easily seen that

\[
K_n(\tilde{A}, \tilde{b}) \subset \text{Ker}(\tilde{A})^\perp.
\]
Thus, all iterates of MinRes/CG with starting vector 0 applied to (9) are elements of $\text{Ker}(\tilde{A})^\perp$. Notice also that (9) has a unique solution in $\text{Ker}(\tilde{A})^\perp$, namely $\tilde{A}^\dagger b$, where $\tilde{A}^\dagger$ denotes the pseudo-inverse of $\tilde{A}$. Thus, if one of these two algorithms terminates (after at most $\dim(K_n(\tilde{A}, b)) \leq p - 1$ iterations), then the corresponding iterate coincides with $\tilde{A}^\dagger b$. Moreover, the iterates of both algorithms converge to $\tilde{A}^\dagger b$, where the rate of convergence (expressed in terms of either the energy “norm” or the norm of the residual) can be bounded in the same way as for non-singular hermitian systems.

In order to prove the above theorem, we consider besides $P = I - bb^*$ the oblique projection operator

$$Q = I - \frac{A^{-1}bb^*}{(A^{-1}b, b)}.$$ 

The following properties are easily verified.

**Lemma 2.** The following hold:

(10) \hspace{1cm} PQ = Q,

(11) \hspace{1cm} QP = P,

(12) \hspace{1cm} PA = PAQ,

(13) \hspace{1cm} A - \frac{bb^*}{(A^{-1}b, b)} = AQ = Q^*AQ,

(14) \hspace{1cm} \tilde{b} = -PAQy_0, \quad \tilde{A}^\dagger \tilde{b} = -Qy_0,

(15) \hspace{1cm} K_n(PA, P(b - Ay_0)) = K_n(\tilde{A}, \tilde{b}).

**Proof.** By the definition of the matrices $P$ and $Q$, and the fact that $\|b\| = 1$, we easily obtain the following four properties:

$$PQ = Q - bb^*Q = Q - bb^* + \frac{b(b^*A^{-1}b)b^*}{(A^{-1}b, b)} = Q,$$

$$QP = P - \frac{A^{-1}bb^*}{(A^{-1}b, b)}P = P - \frac{A^{-1}bb^*}{(A^{-1}b, b)} + \frac{A^{-1}b(b^*b)b^*}{(A^{-1}b, b)} = P,$$

$$PAQ = PA - \frac{Pbb^*}{(A^{-1}b, b)} = PA - \frac{(bb^* - b(b^*b)b^*)}{(A^{-1}b, b)} = PA,$$

$$Q^*AQ = AQ - \frac{bb^*Q}{(A^{-1}b, b)} = AQ - \left( \frac{bb^*}{(A^{-1}b, b)} - \frac{b(b^*A^{-1}b)b^*}{(A^{-1}b, b)} \right) = AQ.$$

Thus, the properties (10)–(13) are shown. By (12), we have $\tilde{b} = -PAQy_0 = -PAQy_0$. Thus, applying (10), we deduce that

$$\tilde{A}^\dagger \tilde{b} = -\tilde{A}^\dagger PAQy_0 = -\tilde{A}^\dagger PAPQy_0 = -\tilde{A}^\dagger \tilde{A}Qy_0 = -PQy_0 = -Qy_0.$$

As the vector $\tilde{b}$ satisfies $P\tilde{b} = \tilde{b}$, we have $K_n(PA, P(b - Ay_0)) = K_n(\tilde{A}, \tilde{b}) = K_n(PAP, \tilde{b}) = K_n(\tilde{A}, \tilde{b})$. Hence the lemma is proved. ■
Proof of Theorem 1. Applying (12), (14), and (10), we see that, for any vector $u$,

$$
\|r(y_0 + Pu)\| = \|PAy_0 + PAPu\| = \|\tilde{A}(Qy_0 + u)\| = \|\tilde{b} - \tilde{A}u\|.
$$

Taking into account (15) and the fact that $K_n(PA, P(B - Ay_0)) = PK_n(PA, P(B - Ay_0))$, for $y_n$ as in (6) we get

$$
y_n - y_0 = \arg\min\{\|r(y_0 + Pu)\| : u \in K_n(PA, P(B - Ay_0))\}
= \arg\min\{\|\tilde{b} - \tilde{A}u\| : u \in K_n(\tilde{A}, \tilde{b})\},
$$
the latter being the $n$th iterate of MinRes with starting vector 0 applied to (9).

Similarly, applying (13), (10), (11), and (14), for any vector $u$ we get

$$
G(y_0 + Pu) = \left( A - \frac{bb^*}{(A^{-1}b, b)} \right) (y_0 + Pu), y_0 + Pu
= (AQ(y_0 + Pu), Q(y_0 + Pu))
= (\tilde{A}Q(y_0 + Pu), Q(y_0 + Pu)) = (\tilde{A}(Qy_0 + u), Qy_0 + u)
= (\tilde{A}(u - \tilde{A}b), u - \tilde{A}b) =: \tilde{G}(u),
$$
and thus for $y_n$ as in (7),

$$
y_n - y_0 = \arg\min\{\|G(y_0 + Pu)\| : u \in K_n(PA, P(B - Ay_0))\}
= \arg\min\{\tilde{G}(u) : u \in K_n(\tilde{A}, \tilde{b})\},
$$
the latter being the $n$th iterate of CG with starting vector 0 applied to (9). Thus Theorem 1 is shown. 

3. Convergence. Before discussing bounds for the rate of convergence of Altman’s methods, let us return to the termination property. As mentioned after Theorem 1, MinRes/CG with starting vector 0 applied to (9) is terminating (with value of the minimum being equal to 0) if and only if the corresponding iterate $y_n - y_0$ coincides with $A^{T}b$, i.e. (compare with (14)),

$$
y_n = y_0 + A^{T}b = y_0 - Qy_0 = \frac{(y_0, b)}{(A^{-1}b, b)} A^{-1}b.
$$
Thus, according to Theorem 1, the well known terminating property for MinRes/CG yields a corresponding termination property for AMinRes/ACG.

However, just as for other Krylov methods, one is more interested in convergence rates before reaching the stage of termination. If one plots the euclidean norm of the error as a function of the number of iterations on a semi-logarithmic scale, then following Nevanlinna [12] one may observe three different ranges which are more or less pronounced for particular examples: In general the curve will be first convex, then linear and finally concave, corresponding to the ranges of sublinear, linear, and superlinear convergence.
In this description we do not take into account the effect of finite precision arithmetic, which of course in practical applications may lead to more complicated convergence curves. In case of a symmetric system (1) with general right-hand sides, the linear convergence behavior is quite well described in terms of the condition number of the underlying matrix of coefficients (see, e.g., [13, Theorem 6.6, Eqn. (6.105), and Corollary 6.1] for MinRes and CG). In contrast, the superlinear convergence behavior depends essentially on the eigenvalue distribution of the underlying matrix of coefficients; see [7–9] for a quantification of this statement. Roughly speaking, the superlinear convergence is pronounced if the eigenvalue distribution, especially for extremal eigenvalues, is far from the arcsine distribution on the convex hull of the spectrum.

Let us study here the behavior of ACG and AMinRes. Using the facts that, for $u \in \text{Ker}(\tilde{A})^\perp$,

$$\|u - \tilde{A}^\dagger b\|^2 \leq \|\tilde{A}^\dagger\| \tilde{G}(u), \quad \|u - \tilde{A}^\dagger b\| \leq \|\tilde{A}^\dagger\| \|b - \tilde{A}u\|,$$

we obtain as a consequence of our findings of the preceding section

$$\left\|y_n - \frac{(y_0, b)}{(\tilde{A}^{-1}b, b)} \tilde{A}^{-1}b\right\|^2 = \left\|y_n - y_0 - \tilde{A}^\dagger b\right\|^2 \leq \begin{cases} \|\tilde{A}^\dagger\|^2 \|r(y_n)\|^2 & \text{for AMinRes}, \\ \|\tilde{A}^\dagger\| G(y_n) & \text{for ACG}. \end{cases}$$

The relative decrease of $\|r(y_n)\|$ or $G(y_n)$ is known from the corresponding classical decrease rates for MinRes/CG [13, Theorem 6.6, Eqn. (6.105), and Corollary 6.1], which are summarized in the following statement.

**Corollary 3 (Linear convergence).** With $\kappa(\tilde{A}) = \|\tilde{A}\| \|\tilde{A}^\dagger\|$ and

$$q := (\sqrt{\kappa(\tilde{A}) - 1})/((\sqrt{\kappa(\tilde{A}) + 1}) < 1$$

we have for the iterates of AMinRes

$$\frac{2}{q^n + q^{-n}} \leq 2q^n,$$

and for the iterates of ACG

$$\sqrt{G(y_n)/G(y_0)} \leq \frac{2}{q^n + q^{-n}} \leq 2q^n.$$

In particular, for $n = 1$ we obtain the upper bound

$$\frac{2}{q^1 + q^{-1}} = \frac{\kappa(\tilde{A}) - 1}{\kappa(\tilde{A}) + 1} \leq \frac{\kappa(A) - 1}{\kappa(A) + 1},$$
the last inequality following from the next lemma. In particular, we recover Altman’s error estimates [1, Eqn. (16)] and [2, Eqn. (12)] for the single-step methods (3) and (5).

Finally, in the range of superlinear convergence, the convergence curve of both methods (6) and (7) (or equivalently MinRes/CG for (9)) is determined by the eigenvalue distribution of $A$, which according to the following result is essentially the same as that for $\tilde{A}$. In what follows we write $\lambda_1(B) \geq \cdots \geq \lambda_p(B)$ for the eigenvalues of any hermitian matrix $B$ of order $p$.

**Lemma 4 (Superlinear convergence).** For the matrices $A$ of (1) and $\tilde{A}$ of (8) we have

$$\lambda_1(A) \geq \lambda_1(\tilde{A}) \geq \lambda_2(A) \geq \lambda_2(\tilde{A}) \geq \cdots \geq \lambda_p(A) > \lambda_p(\tilde{A}) = 0.$$  

**Proof.** It is clear that $b$ is an eigenvector of $\tilde{A}$ corresponding to the eigenvalue 0. Denote by $H_b$ the orthogonal complement of $\text{span}(b)$. Then we find an orthonormal basis of eigenvectors $v_1, \ldots, v_{p-1} \in H_b$, $v_p \in \text{span}(b)$ of the matrix $\tilde{A}$ such that $\tilde{A}v_i = \lambda_i(\tilde{A})v_i$. Thus it remains to show that, for any $i \in \{1, \ldots, p-1\}$,

$$\lambda_{i+1}(A) \leq \lambda_i(\tilde{A}) \leq \lambda_i(A).$$

Define $S_i = \text{span}(v_1, \ldots, v_i)$. Using the Courant–Fischer Minmax Theorem, we get

$$\lambda_i(A) = \max_{\dim(S) = i} \min_{y \in S, y \neq 0} \frac{y^* Ay}{y^* y} \geq \min_{y \in S_i, y \neq 0} \frac{y^* Ay}{y^* y}$$

$$= \min_{y \in S_i, y \neq 0} \frac{y^* P^* A P y}{y^* y} \quad \text{since } S_i \subseteq H_b$$

$$= \min_{y \in S_i, y \neq 0} \frac{y^* \tilde{A} y}{y^* y} = v_i^* \tilde{A} v_i = \lambda_i(\tilde{A}),$$

and hence $\lambda_i(A) \geq \lambda_i(\tilde{A})$. Similarly, with $V_{p-i} = \text{span}(v_i, \ldots, v_{p-1})$ of dimension $p - i$,

$$\lambda_{i+1}(A) = \min_{\dim(S) = p-i} \max_{y \in S, y \neq 0} \frac{y^* Ay}{y^* y}$$

$$\leq \max_{y \in V_i, y \neq 0} \frac{y^* Ay}{y^* y}.$$
\[
= \max_{y \in V_i, y \neq 0} \frac{y^* P^* A y}{y^* y}
\text{ since } V_i \subseteq H_b \]

\[
= \max_{y \in V_i, y \neq 0} \frac{y^* \tilde{A} y}{y^* y} = v_i^* \tilde{A} v_i = \lambda_i(\tilde{A}).
\]

The last two results enable us to compare ACG and CG for the system (1): according to Lemma 4, the convergence behavior in the superlinear range should be similar, but, according to Corollary 3, in the linear range there might be a different behavior, depending on whether \( \kappa(A) = \lambda_1(A)/\lambda_p(A) \) is “much” larger than \( \kappa(\tilde{A}) = \lambda_1(\tilde{A})/\lambda_{p-1}(\tilde{A}) \), this latter link depending on the choice of the right-hand side \( b \). We will confirm these claims by some numerical experiments reported in Section 5.

4. The algorithm ACG. In the CG algorithm applied to (9) one constructs recursively \( \tilde{A} \)-conjugate bases \( p_0, \ldots, p_{n-1} \) of \( K_n(\tilde{A}, \tilde{b}) \), leading to one-dimensional minimization problems and thus coupled short-term recurrences. Observing that

\[
\tilde{r}_n := \tilde{b} - \tilde{A}(y_n - y_0) = \tilde{b} - PA(y_n - y_0) = -r(y_n),
\]

we obtain from Theorem 1 the following coupled system of recurrence relations (we keep the notations of CG as stated, e.g., in [13, Algorithm 6.17]) for the iterates \( y_n \) of ACG:

**Initialize** \( \tilde{r}_0 = p_0 = -r(y_0) \)

**Compute for** \( n = 0, 1, \ldots \) **until** \( \|\tilde{r}_n\| \) **is sufficiently small**

\[
\alpha_n = \frac{\tilde{r}_n, \tilde{r}_n}{(\tilde{A} p_n, p_n)} = \frac{\tilde{r}_n, \tilde{r}_n}{(r(p_n), p_n)} = \frac{(\tilde{r}_n, \tilde{r}_n)}{(\tilde{A} p_n, p_n)},
\]

\[
y_{n+1} = y_n + \alpha_n p_n, \quad \tilde{r}_{n+1} = \tilde{r}_n - \alpha_n \tilde{A} p_n = \tilde{r}_n - \alpha_n r(p_n),
\]

\[
\tilde{\beta}_n = \frac{(\tilde{r}_{n+1}, \tilde{r}_{n+1})}{(\tilde{r}_n, \tilde{r}_n)}, \quad p_{n+1} = \tilde{r}_{n+1} + \tilde{\beta}_n p_n.
\]

As a consequence, for the sequence \( x_n = y_n/(Ay_n, b) \) approaching the solution of (1) we obtain the residual

\[
r_n := b - A x_n = \frac{1}{(Ay_n, b)}((Ay_n, b)b - Ay_n) = -r(y_n)/(Ay_n, b) = \tilde{r}_n/(Ay_n, b),
\]

and the substitution \( z_n = p_n/(Ay_n, b) \) leads to

\[
x_{n+1} = \frac{(Ay_{n+1}, b)}{(Ay_{n+1}, b)}(x_n + \alpha_n z_n) = \frac{x_n + \alpha_n z_n}{1 + \alpha_n(Az_n, b)},
\]
\[ z_{n+1} = r_{n+1} + \tilde{\beta}_n \frac{(Ay_n, b)}{(Ay_{n+1}, b)} z_n = r_{n+1} + \beta_n(1 + \alpha_n(Az_n, b))z_n, \]

\[ \beta_n = \frac{(r_{n+1}, r_{n+1})}{(r_n, r_n)}. \]

Hence we get following equivalent formulation of ACG:

**Initialize** \( r_0 = z_0 = b - Ax_0 \)

**Compute for** \( n = 0, 1, \ldots \) until \( ||r_n|| \) is sufficiently small

\[ \alpha_n = \frac{(r_n, r_n)}{(Az_n, z_n)}, \quad \nu_n := 1 + \alpha_n(Az_n, b), \]

\[ x_{n+1} = \frac{1}{\nu_n} (x_n + \alpha_n z_n), \]

\[ r_{n+1} = \frac{1}{\nu_n} (r_n - \alpha_n r(z_n)) = \frac{1}{\nu_n} (r_n - \alpha_n PAz_n) \]

\[ = \frac{1}{\nu_n} (r_n - \alpha_n [Az_n - (Az_n, b)b]), \]

\[ \beta_n = \frac{(r_{n+1}, r_{n+1})}{(r_n, r_n)}, \quad z_{n+1} = r_{n+1} + \nu_n \beta_n z_n. \]

Notice that this method, as MinRes and CG, requires one matrix-vector product by iteration.

We conclude this section with the observation that the last identity for \( r_{n+1} \) in the algorithm ACG can be written as

\[ r_{n+1} = \frac{1}{\nu_n} r_n - \frac{\alpha_n}{\nu_n} \left( Az_n - \frac{\nu_n - 1}{\alpha_n} b \right) = \frac{1}{\nu_n} \left( r_n - \alpha_n Az_n \right) + \left( 1 - \frac{1}{\nu_n} \right) b. \]

For \( n = 0 \) this observation gives rise to the following interpretation: the residual of the one-step version (5) of ACG is obtained by taking a convex combination of the residual of steepest descent (i.e., one iteration of CG applied to (1)) and the original residual. Such a relaxation interpretation was already mentioned by Altman in [4].

**5. Numerical experiments.** Let us now give some numerical results illustrating the ACG method and compare it to the classical conjugate gradient algorithm for solving \( Ax = b \) with two different kinds of test matrices \( A \). All the computations were performed in MATLAB and all norms are Euclidean.

We first present an example of a system (1) with a matrix \( A \) of dimension \( p = 50 \) resulting from the discretization of the one-dimensional Laplacian on \([-1, 1] \), the right-hand side \( b \) and the starting vector \( y_0 \) being chosen randomly. Here the eigenvalue distribution of \( A \) approaches the worst case of an arcsine distribution, and hence superlinear convergence should only
occur for very special right-hand sides \(b\) (compare with [9]). As expected, we observe in Figure 1 that the convergence rate is essentially linear, up to

![Figure 1. ACG (dashed line) versus CG (solid line) for \(A = \text{tridiag}([-1, 2, -1])\) of dimension 50 resulting from the discretization of the one-dimensional Laplacian.]

the stage where the termination property of CG/ACG suddenly gives convergence. We also notice that, by Lemma 4, the quantity \(\kappa(\hat{A})\) lies between \(\kappa(A) = \lambda_1(A)/\lambda_p(A)\) and \(\lambda_2(A)/\lambda_{p-1}(A)\), which for our example give the numerical values \(1.05 \cdot 10^3\) and \(0.26 \cdot 10^3\). Thus the condition number of \(\hat{A}\) is not essentially smaller than that of \(A\), and the convergence behavior of CG and ACG should be similar. This is clearly confirmed by the results presented in Figure 1: for this example we find that ACG, compared to CG, allows one to gain only one iteration.

The second group of examples were performed using the matrix \(A = QDQ^*\), where

\[
Q = (I - 2w_3w_3^*)(I - 2w_2w_2^*)(I - 2w_1w_1^*),
\]

\(w_1, w_2,\) and \(w_3\) are unitary random vectors, \(D = \text{diag}(\lambda_1, \ldots, \lambda_p)\) is a diagonal matrix whose components are \(\lambda_i = \varepsilon + (i - 1)\) for \(i = 1, \ldots, p\), and \(\varepsilon > 0\) is a scalar which will vary below. In our tests reported below we use \(p = 1000\), the starting point \(y_0 = (1, \ldots, 1)^* \in \mathbb{R}^p\) for ACG, and the starting point \(x_0 = (1, \ldots, 1)^* \in \mathbb{R}^p\) for CG. The solution \(x\) of system (1) (and hence the right-hand side \(b = Ax\)) will be chosen either randomly, or in terms of the eigenvector \(v_i\) corresponding to the eigenvalue \(\lambda_i(A)\) of \(A\).

In Table 1, we report the results for seven different choices of parameters, namely, the choice of the variable \(\varepsilon\) and/or the solution \(x\), the resulting

condition numbers of the matrices $A$ and $\tilde{A}$, and the resulting number of iterations used to obtain an error norm $\|x_k - x\| \leq 10^{-8}$ by the CG and the ACG method.

We first provide some explanation for the CG convergence behavior for these seven examples. The convergence behavior for the case of equidistant eigenvalues and $\varepsilon = 1$ and general right-hand sides was considered in [7, Corollary 3.2]; here one essentially has only superlinear convergence for CG, and no range of linear convergence occurs (see also the plot of Example VII in Figure 4). For $\varepsilon$ approaching zero, the condition number of $A$ becomes worse. Here the superlinear convergence is delayed by some non-trivial range of linear convergence, corresponding to the quasi-horizontal part on the left-hand side of the CG curves for examples I, II and III (which are essentially the same) and V and VI (again essentially the same).

Concerning the convergence behavior of ACG, we note that, for small $\varepsilon$, there is an important gap between $\kappa(A) = \lambda_1(A)/\lambda_p(A)$ and $\lambda_2(A)/\lambda_{p-1}(A)$, and thus a potential improvement of ACG on CG in the range of linear convergence. Indeed, for examples I, II and V we get an essential improvement for the number of iterations (see Table 1 and Figures 2 and 3). However, for general right-hand sides as in examples III, IV, and VI, no essential improvement is found even in the range of linear convergence (compare with Table 1 and Figures 3 and 4), confirming our theoretical observations at the end of Section 3. Moreover, for $\varepsilon = 1$ and hence well conditioned $A$ as in example VII (see Figure 4), the two methods CG and ACG behave identically.

We terminate our discussion of this second group of examples by some concluding remarks. The work in [7–9] is based only on the (asymptotic) eigenvalue distribution, and gives some weak asymptotics for the error of Krylov subspace methods. For many examples, the bounds obtained in [7] not only describe the error asymptotically, but also provide an upper bound without passing to the limit, yet this latter experimental observation has no theoretical justification. In our case, it seems that, in the superlinear range, the slopes of all twelve convergence curves (CG and ACG) only depend on
Fig. 2. ACG (dashed line) versus CG (solid line), examples I (top) and II (bottom)
Fig. 3. ACG (dashed line) versus CG (solid line), examples III (top) and V (bottom)
Fig. 4. ACG (dashed line) versus CG (solid line), examples VI (top) and VII (bottom)
the ratio of the iteration index and of $p$, and coincide with the slope pointed out in [7]. But for the error there seems to be an additional multiplicative factor depending on the condition number, and, more importantly, due to this factor, the beginning of superlinear convergence seems to be delayed. In this context we should mention that the effect of ill-conditioning of the matrix of coefficients (which is related to [7, condition (iii)]) was essentially neglected in [7], and its exact role for (non-asymptotic) upper bounds for the CG in the superlinear range remains open.

Appendix: Representation of the quadratic form. Denote by $H_b$ the orthogonal complement of span($b$). In [2], Altman uses the quadratic form

\begin{equation}
    z \in H_b : \quad F(z) := (r^{-1}(z), z).
\end{equation}

In order to justify that this formula makes sense, Altman first shows that the restriction $r : H_b \mapsto H_b$ is hermitian, self-adjoint and positive-definite, and thus the inverse of $r$ exists on $H_b$. In fact, for $u \in H_b$ we have $r(u) = PAu = PAPu = \tilde{A}u$, and thus $r^{-1}(u) = \tilde{A}^lu$.

This observation allows us to relate the quadratic form $F$ of (16) to the quadratic form $G$ of (4): for any vector $y$ we have, according to (12) and (10),

\begin{align*}
    F(r(y)) &= (\tilde{A}^t r(y), r(y)) = (\tilde{A}^t PAy, PAy) = ((PA)^* \tilde{A}^t PAy, y) \\
    &= ((PAQ)^* \tilde{A}^t PAQy, y) = (Q^* \tilde{A} \tilde{A}^t Qy, y) \\
    &= (Q^* \tilde{A}Qy, y) = (Q^* AQy, y),
\end{align*}

and thus (13) implies that $F(r(y)) = G(y)$.
